Supporting Information

ABSTRACT: Biological samples exhibit huge molecular diversity over large concentration ranges. Titrating a given compound in such mixtures is often difficult, and innovative strategies emphasizing selectivity are thus demanded. To overcome limitations inherent to thermodynamics, we here present a generic technique where discrimination relies on the dynamics of interaction between the target of interest and a probe introduced in excess. Considering an ensemble of two-state exchanging reactants submitted to temperature modulation, we first demonstrate that the amplitude of the out-of-phase concentration oscillations is maximum for every compound involved in a reaction whose equilibrium constant is equal to unity and whose relaxation time is equal to the inverse of the excitation angular frequency. Taking advantage of this feature, we next devise a highly specific detection protocol and validate it using a microfabricated resistive heater and an epifluorescence microscope, as well as labeled oligonucleotides to model species displaying various dynamic properties. As expected, quantification of a sought for strand is obtained even if interfering reagents are present in similar amounts. Moreover, our approach does not require any separation and is compatible with imaging. It could then benefit some of the numerous binding assays performed every day in life sciences.

INTRODUCTION

Quantifying a given species in a complex medium of living origin is currently encountered in many medical and pharmaceutical activities such as molecular diagnosis and drug screening. Moreover, extensive characterization of the cellular content is the workhorse of scientific fields such as genomics, proteomics, and metabolomics. Yet these analytical tasks represent a tremendous challenge, as crude biological samples typically contain 10⁴—10⁶ components of the same kind (e.g., RNAs, proteins) at concentrations covering up to 10 orders of magnitude. Improvement in assay selectivity is therefore required to avoid as much as possible the cumbersome pre-treatments today necessary prior to any specific detection.

Directly “counting” intrinsic labels such as functional groups is not appropriate to investigate the considered mixtures because they are mostly made of biopolymers that share the same building blocks in the same proportions. In fact, this type of approach results in spectral crowding, and unambiguous species identification can be achieved only through coupling with methods emphasizing physicochemical criteria (e.g., separation

for mass spectrometry or correlation analysis for IR absorption). Besides such complicated multidimensional analyses, titration is then a valuable strategy because one just has to observe a single reagent selectively probing the compound of interest. Furthermore, in the present context there it benefits from the high specificity that characterizes molecular recognition in biology.

Binding assays, which rely on thermodynamics for discrimination, are actually widespread. Whereas “mix-and-read” tests are homogeneous and consequently convenient, the advent of microarrays has yielded unprecedented multiplexing capabilities, with thousands of titrations being performed in parallel. However, species concentrations are often overestimated because labeling reagents are insufficiently rinsed away or because nonspecific adsorption onto solid supports is poorly controlled. Additionally, in a mixture of similar components, a single probe is anticipated to display close affinities for several targets. Thus,

and 6. τ the adimensional relaxation time respectively, are plotted versus the equilibrium constant K phase oscillations in A1 concentration, improved. We here propose to increase the number of dis-
tion to overcome such limitations, detection selectivity has to be

Figure 1. Theoretical computation of the response of a two-state exchanging reactant A1 ⇄ A2 submitted to thermal harmonic forcing. The normalized amplitudes of the in-phase and out-of-

Figure 1 displays, for a fixed value of ΔH, the dependence on K0 and τ0ω of A1sin/A and −A1cos/A. Interestingly, the amplitude in quadrature exhibits a single maximum centered on

K0 = 1 and τ0ω = 1

with full widths at half-maximum 4√2 along K0 and 2√3 along τ0ω. Due to the symmetry of the sinusoidal forcing, a first condition for this “resonance” to occur is that A1 and A2 are in equal proportions. Indeed, the temperature modulation then causes the largest relative variations of their concentrations. Second, the reaction relaxation time has to match the oscillation period. In fact, in the 1/τ0ω ≪ ω regime, the exchange is slow compared to the temperature variations, the {A1, A2} couple has not enough time to respond: both A1sin and A1cos vanish. Conversely, in the 1/τ0ω ≫ ω regime, the A3 concentration keeps pace with the thermal excitation: A1sin plateaus at its highest values, whereas A1cos cancels.

The existence of a peaked response for A1cos is significant to quantify a given targeted couple {A1, A2} in an unknown mixture of reactive compounds {A1, A2} associated with different values of equilibrium constants Kj, relaxation times τj, and total concentrations Aj.

We consider a titration in which an analyte A1 reacts with a probe P to form a product A2, the forward and backward rate constants being respectively denoted k+ and k−. If the concentration P is such that P is in great excess, we can model the reaction as a two-state exchange:

A1 + k− A2

A1 + k+ A2

(1)

with k+ = k0P. A sinusoidal modulation of the temperature T is then applied around T0, at angular frequency ω and with a small amplitude βT0:

T = T0[1 + β sin (ωt)] (β ≪ 1)

(2)

Following Arrhenius, we have k±(T) = r± exp[−E±/RT], where R is the ideal gas constant. As both the pre-exponential factors r± and the activation energies E± are assumed to not vary with T, a first-order expansion in the perturbation yields k±(t) = k±0 [1 + β0 sin(ωt)] with k±0 = r± exp[−E±0] and ϵ± = E±/ RT0. Beyond the relaxation time τ0 = 1/(k0 + k−), one enters into the forced and permanent regime where the concentration A1(t) in each species A1 obeys:

A1(t) = A0 + A0 sin(ωt) + A0 cos(ωt) (3)

In the latter equation, A0 is the A1 concentration at chemical equilibrium at T0:

A0 = A − A0 = A

1 + K0 (4)

where A is the total concentration in the {A1, A2} couple and K0 = k0/k− is the reaction 1 equilibrium constant at T0. Moreover, the amplitudes of the oscillating terms at angular frequency ω, in phase and out of phase with the temperature, are respectively given by eqs 5 and 6:

A1sin = A1sin = \frac{ΔH}{RT0(1 + K0)} \frac{K0}{1 + (τ0ω)^2} A

(5)

A1cos = A1cos = \frac{ΔH}{RT0(1 + K0)} τ0ω A

(6)

where ΔH = E+ − E− is the standard enthalpy of the exchange reaction.
where we assume that (i) only the $A_t$ species participate in the overall signal, for instance, because fluorescence emission is quenched in $A_{2i}$; (ii) the output contribution of each compound linearly depends on its concentration $A_t$ with a proportionality factor unique to all the $A_{ij}$; and (iii) all exchanges have a similar $\Delta H$ value: the latter parameter is indeed expected to vary just over 1–2 orders of magnitude, whereas $K_l^0$ and $r_0^f$ can typically span 10 orders of magnitude because of their exponential dependence on the reaction enthalpy. In the absence of any information about composition, the target concentration has to be evaluated by presuming that the signal from the whole sample is solely due to the sought for reactant. Therefore, the titration result $A_t^0$ is always an overestimate of $A_t$. For example, a protocol relying on equilibrium at constant temperature $T_d$ leads to

$$A_t^{\text{tit}-0} = A_t + \sum_{i \neq t} \left( \frac{A_{t_i}^0}{A_t} A_i \right) = A_t + \sum_{i \neq t} \left( \frac{1 + K_l^0}{1 + K_l} A_t A_i \right) \tag{8}$$

Noteworthily, the second component of the right term can hardly be made negligible, which means that the contribution of the species of interest cannot be maximized among those of the interfering compounds. In contrast, looking at the out-of-phase response to a thermal excitation yields

$$A_t^{\text{tit}-\cos} = A_t + \sum_{i \neq t} \left( \frac{A_{t_i}^{\cos}}{A_t} A_i \right) \tag{9}$$

Provided the eq 7 resonant conditions are satisfied for $\{A_{t_1}, A_{t_2}\}$, we have $(A_{t_i}^{\cos}/A_t) \gg (A_{t_i}^{\cos}/A_t)$ whenever $i \neq t$ (Figure 1b and Table 1S in the Supporting Information). Thus, the signal issued from the targeted couple can now dominate the one from the other couples. Figure 2 illustrates for various equimolar mixtures the superiority of this second strategy over equilibrium measurements: whereas all the $A_t^{\text{tit}-0}$ values are several times larger than the actual $A_t$ concentration, the discrepancy between $A_t^{\text{tit}-\cos}$ and $A_t$ becomes vanishingly small as soon as the $\{A_{t_1}, A_{t_2}\}$ depart from $\{A_{t_1}, A_{t_2}\}$ in the $(K_l^0, r_0^f)$ plane.

**Experimental Section**

**Reagents and Solutions.** Solutions were prepared using water purified through a direct-Q5 system (Millipore, Billerica, MA). 4-(2-Hydroxyethyl)-1-piperazineethanesulfonic acid (Hepes), Mg(OH)$_2$, and NaOH were purchased from Sigma–Aldrich (St. Louis, MO).

Poly(dimethylacrylamide) (PDMA) of average molecular mass $\sim 3$ MDa, was given by J. Weber (Institut Curie, Paris, France).

Solutions were prepared using water purified through a direct-Q5 system (Millipore, Billerica, MA). 4-(2-Hydroxyethyl)-1-piperazineethanesulfonic acid (Hepes), Mg(OH)$_2$, and NaOH were purchased from Sigma–Aldrich (St. Louis, MO).

Poly(dimethylacrylamide) (PDMA) of average molecular mass $\sim 3$ MDa, was given by J. Weber (Institut Curie, Paris, France).

This polymer was introduced in all solutions to prevent, thanks to dynamic coating, biomolecules adsorption onto the micro-device walls.

The oligonucleotides were synthesized on the 1 μmol scale, conjugated, and double-HPLC-purified by IBA (Göttingen, Germany). With a $5'–3'$ orientation, boldface capitals to designate the bases involved in hybridization, and bhq, fam, rhx, and tex to respectively designate the black hole quencher 2, fluorescein, rhodamine green, and Texas red labels, the single-stranded sequences read $A_{t_1} = \text{rhg-CTTTGTTTGTG}; P = \text{AGAGCCCATGAACAAAGGAG}; A_{t_{1i}} = \text{rhg-T}_{10}1,t; A_{t_{i}} = \text{fam-T-GATAGT}_{10}C$-TATC- tex; and $M = \text{tex-T-GATAGT}_{10}C$-TATC-bhq. The concentration of the stock solutions was estimated by measuring their absorption at 260 nm on a UVikon-940 spectrophotometer (Kontron, Zürich, Switzerland). This determination was performed at 20°C and we relied on the molar absorption coefficients provided by the manufacturer.

**Thermal Control.** To generate temperature oscillations in the solution to be analyzed, we made use of a previously described resistor. As this heater, 340 μm $\times$ 340 μm large, was micromachined in a 400 nm indium tin oxide (ITO) film of resistivity 10 $\Omega$ cm that had been deposited on a 550 μm thick glass wafer (Figure 3). More precisely, the fabrication was a three-step process: (i) the hot plate feature was defined by optical lithography and transferred into the thin film semiconductor by ion beam etching; (ii) a second photolithography followed by a standard lift-off procedure yielded gold leads that enabled to contact the active zone with the macro-world; (iii) the whole heater was encapsulated in a 800 nm thin layer of silica to prevent any electrochemical degradation of the sample. Once electrical connectors had been welded, the device was completed by assembling the fluidic system: a PDMS stamp including 35 μm large and 10 μm high channels, separated by 20 μm walls.

In operation, the bottom glass surface of the microchip was placed on a 0.4 mm thick copper disk in which a 3 mm large slit had been opened for observation with the objective. This metal holder was itself mounted on an aluminum block thermostated at $\pm 0.2$ K with thermoelectric Peltier devices (CP 1.0-63-05).
L-RTV; Melcor, Trenton, NJ). The stage temperature was monitored with a TCS610 thermistor (Wavelength Electronics, Bozeman, MT) and the feedback loop was driven by a MPT1000 temperature controller (Wavelength Electronics), which received instructions from the computer through a usb-1208 fs I/O board (Measurement Computing, Norton, MA).

For experiments where thermal excitation was required, we injected a sinusoidal current of peak amplitude 18 mA in the ITO resistor using a function generator, either a DS360 (Standford Research Systems, Sunnyvale, CA) or a 33220A−20 MHz (Agilent, Santa Clara, CA). It resulted in a 0.6-mm-thick gold microheater, which was fabricated using standard photolithography techniques (Agilent, Santa Clara, CA). The microheater was driven with 18 mA AC current at various frequencies from 0.02 to 2 Hz and the temperature was controlled using a LabVIEW program (National Instruments, Austin, TX). The power resistance (RLP 1%, Vishay-Serfnice, Germany) was used to control the homogeneity of the thermal excitation. The temperature range was between 0.54 and 59 rad/s

Fluorescence Microscopy and Video Acquisition. Imaging was achieved using a previously reported homemade dual-view epifluorescence microscope, whose optics were arranged as follows. The source light was first passed through a multiband filter for selective excitation of both rhodamine green and Texas red (FF01-525/30–25; Semrock, Rochester, NY). A multiedge dichroic mirror (FF505/606-Di01; Semrock) and a 10× objective (Fluar NA 0.5; Zeiss, Le Pecq, France) were then used to perform epifluorescence illumination. The emitted light was subsequently collected and divided in two by a first 585DCXR dichroic mirror (Chroma Technology, Rockingham, VT). The resulting optical rays associated with the green (g) and red (r) channels were next filtered by relying respectively on FF01-525/30–25 and FF01-628/32–25 band-pass filters (Semrock). Finally, with the help of a second 585DCXR dichroic mirror, the two-color image was reconstructed on the chip of a CCD camera, either a BM-141 GE (JAI, Copenhagen, Denmark) or a Luca-R (Andor Technology, Belfast, U.K.). The field of view was ~0.5 mm for each color channel. We could also estimate that, at similar dye concentrations, rhodamine green contamination accounted for less than 10% of the Texas red signal in the red acquisition window.

To derive an expression for the intensity of the images collected with the camera in each color channel c of the dual-view system, we consider a two-state exchange like that in eq 1. Fluorescence being emitted by both A species, after subtraction of the background signal, it yields

$$F^c(x, y, T) = E(x, y) C(x, y) \left[ Q_{\lambda} A_1(T) + Q_{\lambda} A_2(T) \right]$$

where $E(x, y)$ is the illumination intensity arriving on the sample and $C(x, y)$ is the instrumental transfer function accounting for the collection of photons and their conversion in electrical signal. Noticeably, $E$ and $C$ vary with the pixel coordinates, whereas concentration profiles in both reagent and product are assumed to be homogeneous. In eq 10 the $Q_{\lambda}$ brightnesses are introduced, defined as

$$Q_{\lambda}^c = \int \varepsilon(\lambda) \varepsilon_{A1}(\lambda) \, d\lambda \times \int \phi_{A1}(\lambda) \phi_{A1}(\lambda) \, d\lambda$$

where $\varepsilon_{A1}$ and $\phi_{A1}$ are the A1 molar absorption coefficient and fluorescence quantum yield, respectively. On the other hand, the two functions $\varepsilon$ and $\phi$, whose integrals are equal to 1, hold for the variation with $\lambda$ of the excitation and detection efficiencies, respectively. Finally, the 2.3 factor corresponds to ln 10; it originates from developing at first order the Beer−Lambert law to retrieve the intensity of light absorbed by the sample. As demonstrated in a previous paper, $E$, $C$, and $Q_{\lambda}$ depend only weakly on $T$. In the case where a temperature modulation of small amplitude, $\beta T_0 \sin(\omega t)$, is applied around $T_0$, eq 10 can further be developed by use of eqs 3, 5, and 6. It is here important to remark that, as proved by the measurements reported in Figure 4S in the Supporting Information, both $T_0$ and $\beta$ are even over the heater surface under study. Similarly, the thermal excitation shows no phase shift whatever the values of $x$ and $y$. Thus, for experimental conditions that minimize photobleaching, the temporal variation of the signal from each pixel is

$$F^c(x, y, t) = F^0(x, y) + \beta F^1(x, y) \sin(\omega t + \phi^c + \phi)$$

dx.doi.org/10.1021/ac1026034 | Anal. Chem. 2011, 83, 2476–2484
with the angle \(\phi\) reflecting the fact that the present setup does not allow us to precisely phase CCD recording and Joule heating. After \(Z_0^A\) and \(Z_0^\perp\) are introduced as \(^{48}\)

\[
Z_0^A = \frac{Q_{A_2}}{1 + (\omega K_A^0)} + \frac{Q_{A_1}}{1 + (\omega K_A^0)}(13)
\]

\[
Z_0^\perp = \frac{1}{1 + (\omega K_A^0)}(14)
\]

the other terms of eq 12 are given by

\[
F^\perp(x, y) = E(x, y) C'(x, y) Z_0^A A(15)
\]

\[
F^\parallel(x, y) = E(x, y) C'(x, y) Z_0^\perp A(16)
\]

\[
\phi^* = -\arctan(t^*\omega)(17)
\]

In general, video acquisition speed is restricted by the frequency of the camera: \(f_{video} = 30.1\) and \(36\) Hz for the present BM-141 GE and Luca-R models, respectively. However, we chose to transfer at a constant rate only \(2n\) frames per temperature oscillation, thus limiting the amount of data to be subsequently processed. For \(\omega/2\pi \leq 0.375\) Hz, we typically set \(n = 8\), yet its value had to be lowered in the case of faster modulations (for instance, down to 4 at \(\omega/2\pi = 3.76\) Hz). Furthermore, to improve the signal-to-noise ratio, recording was carried on over several periods; the number of collected images was \(\sim 250\) for relaxation time measurements and \(\sim 5000\) for quadrature detection. All the frames having the same index modulo \(2n\) were next averaged together to yield a single oscillation-long movie. Therefore, thanks to eq 12, the intensity profile corresponding to the \(k\)th image is now given by

\[
F^k(x, y, k) = F_0^\perp(x, y) + \beta F_0^\parallel(x, y) \sin\left(\frac{k\tau}{n} + \phi^* + \phi\right)(18)
\]

Incidentally, because an even number of images was regularly sampled over a period, one also has \(\langle F^k(x, y, k)\rangle_k = F_0^\perp(x, y)\).

Using such a data collection protocol implied two experimental constraints. First, the camera and the temperature excitation frequencies had to be commensurable. More precisely, with an image pickup rate of \(1/p\), two successive acquisitions were separated by a time lapse of \(p/f_{video}\) seconds. Thus, as \(2n\) video frames were transferred per period of \(2\pi/\omega\) seconds, it resulted in \(\omega = n f_{video}/np\). The values accessible for the heating pulser were in limited number and the function generator that drove the current flowing through the ITO resistor then had to be tuned accordingly. The second constraint was for the acquisition system to be able to collect and process a large number of video frames. We here relied on a homemade electronic setup, associated with a dedicated program written in C, to sort and average in real time the images sent by the CCD camera.

Relaxation Time Measurement. The \(A_{11} + P \equiv A_{12}\) dynamics was investigated by studying how a mixture of the corresponding molecules responds to small temperature oscillations. As we worked with an excess of probe, \(^{46}\) the fluorescence signal collected in the green channel of the microscope, \(F^k(x, y, k)\), thus obeyed the expressions derived for a two-state isomerization, that is, eqs 12–18. In this experiment, artifacts related to thermal transfer caused us to also introduce in solution the molecular thermometer \(M\) (vide infra). It hence provided in the red video channel a response, \(F^k(x, y, k)\), that similarly follows eqs 12–18.

Renormalizing the one-period-long movies by \(\langle F^k(x, y, k)\rangle_k\) first enabled us to correct them from defects associated with inhomogeneous illumination and photon collection. After spatial averaging over a \(125 \times 150\) pixels area, it resulted in two

\[
F_{norm}(k) = 1 + \beta Z_0^\perp Z_0^A \sin\left(\frac{k\tau}{n} + \phi^* + \phi\right)(19)
\]

curves that could subsequently be fitted to sinusoids in order to provide the \(\beta Z_0^A/Z_0^\perp\) amplitudes (Figure 2S, Supporting Information). Next, to get rid of the experimental bias linked to the variation of \(\beta\) with \(\omega\), we computed \(\phi^{\perp/\parallel}\) as the ratio between the green and red modulation depths: \(\phi^{\perp/\parallel} = (\beta Z_0^\perp/Z_0^\perp)/(\beta Z_0^A/Z_0^A)\). Indeed, this operation allowed us to obtain a function whose dependence on the angular frequency is contained only in a \(1/[1 + (t_0^\perp/\omega)^2]^{1/2}\) term (see Supporting Information). Finally, the relaxation time \(t_0^\perp\) was easily extracted by fitting the \(\phi^{\perp/\parallel}(\omega)\) transfer function (Figure 4b).

Quadrature Imaging. For the titration, the red-emitting molecular thermometer \(M\) was still added to the green-emitting sample to be analyzed. It therefore permitted access to the phase \(\phi\) in a distinct color channel.

Adding the fluorescence issued from the various \(A_0\) species yields an oscillating signal, \(F^k(x, y, k)\), whose amplitude in quadrature, \(\beta \phi^{\perp/\parallel}(x, y)\), is proportional to the sum of all the individual out-of-phase contributions, \(\langle Q_{A_2}^k - \overline{Q}_{A_1}^k \rangle A_{11}^{11\perp}(x, y)\). To emphasize \(A_{11}^{11\perp}\), we demodulated a one-period-long movie with a \(-\pi/2\) phase delay.\(^{24,25}\) More specifically, we first subtracted \(\langle F^k(x, y, k)\rangle_k\) to the entire video. Then, we divided the resulting frames by a flat-field one, \(F^k(x, y, k)\), in order to correct them from optical artifacts (see Supporting Information for details). Finally, each image was multiplied by \(\sin[(k\tau/n) + \phi - (\pi/2)]\) and the whole movie was averaged to give

\[
F_{quad}^k(x, y) = \sum_t (Q_{A_2}^k - \overline{Q}_{A_1}^k) A_{11}^{11\perp}(x, y) (20)
\]

Under the assumptions of similar concentrations, standard enthalpies of reaction, and brightness differences for all the reactive couples, the previous equation could further be transformed in \(F_{quad}^k(x, y) \approx A_{11}^{11\perp}(x, y)\). Indeed, resonance conditions had been selected to selectively stress on \(A_{11}, A_{03}\) and the interfering species were here such that \(A_{11}^{11\perp}(x, y)\) was vanishing for \(t \neq t_0\). Each pixel of the image therefore exhibited an intensity directly proportional to the \(A_1\) concentration and an absolute estimate for the latter could be obtained by relying on the channel 4 calibration standard (Figure 5).

Thermodynamic Parameters Measurement. The standard enthalpy and entropy of hybridization between the target and its probe, \(\Delta H^p\) and \(\Delta S^p\), were determined via a thermal denaturation experiment in which the temperature of the microscope stage was ramped from 10 to 45 °C and the green fluorescence emission from an \(A_{11} + P\) mixture was accordingly recorded. The two species being at respective initial concentrations \(A_1\) and \(yA_0\), one can solve the mass action equation to obtain

\[
\frac{F_{quad}(T)}{F_{iso}(318 \text{ \text{K}})} = 1 + \left(\frac{Q_{A_2}^k}{Q_{A_1}^k} - 1\right) \times \frac{[(y + 1)K_0^p A_1 + 1] - \sqrt{[(y + 1)K_0^p A_1 + 1]^2 - 4y(K_0^p A_1)^2}}{2K_0^p A_1}(21)
\]
The signal was here normalized by its value at 318 K where no $A_2$ is present (see Supporting Information). In the latter equation $K_{p}^{+}$ is the $A_1 + P \rightleftharpoons A_2$ equilibrium constant:

$$K_{p}^{+} = \exp \left( -\frac{\Delta_{p}^{\text{H}} - T \Delta_{p}^{\text{S^p}}}{RT} \right)$$

Consequently, fitting the experimental data yielded the two sought for thermodynamic parameters (Figure 4a).

## RESULTS AND DISCUSSION

To experimentally evaluate the “temperature modulation and quadrature detection” approach for detection in a mixture, we chose to selectively titrate a fluorescent oligonucleotide using a hybridization reaction, this analysis being performed in the presence of other compounds similarly labeled. More precisely, we targeted a rhodamine green-conjugated sequence, $A_{11}$, which forms a much less fluorescent duplex, $A_{22}$, with the unlabeled probe, P. As putative interfering species, we adopted two green-emitting oligonucleotides: $A_{33}$, a labeled poly(thymidine) strand that can be considered as a representative nonreactive sequence, and $A_{44}$, a molecular beacon presently envisaged as a reagent engaged in an exchange faster than the targetted one, although it yields a paired structure with a similar stability. Indeed, in the considered temperature range the opening—closing relaxation time of the latter species, $\tau_{\text{MB}}$, has been measured below 1 ms\(^{42}\) and its equilibrium constant, $K_{\text{MB}}$, lies between 0.5 and 5.\(^{47}\) As we will see in the following, when $P$ varies between 3 and 7 $\mu$M, the corresponding values for the probe—target couple are $\tau_{p}^{0} \sim 30–300$ ms and $K_{p}^{0} \sim 0.3–6$ (see Table 2S in the Supporting Information).

The samples to be analyzed were injected in the PDMS channels, 35 $\mu$m wide and 10 $\mu$m high, of a dedicated device (Figure 3).\(^{35}\) Although thermal excitation can be obtained by IR laser heating,\(^{36,34}\) we here relied on the Joule effect implemented on the bottom glass substrate, our chip is fully compatible with epifluorescence imaging. Using a dual-view optical setup,\(^{39}\) we could selectively titrate green-labeled species while mapping the temperature field with $M$, a red-emitting molecular thermometer that was designed after the previously published MB\(^{42}\) and that responds instantaneously to any of the thermal excitations applied in the present work. The average temperature as well as the oscillations’ amplitude and phase were proved uniform over the 100 $\mu$m $\times$ 300 $\mu$m observation area (Figure 4S, Supporting Information), demonstrating that thermal transfer can be satisfactorily engineered when this kind of resistive element is utilized in combination with a holder acting as a heat reservoir.

We first performed a series of preliminary measurements devoted to identify the resonance conditions associated with the $A_1 + P \rightleftharpoons A_2$ titration. In fact, in the context of a bimolecular reaction and according to the criteria given in eq 7, we had to look for an angular frequency and a probe concentration that respectively verify $\omega_{\text{exc}}^{2} = 1/\tau_{p}^{0}$ and $P_{\text{exc}}^{\text{P}} = 1/K_{p}^{0}$, where $K_{p}^{0}$ is the pairing equilibrium constant at $T_{0}$. By employment of the microscope and its thermostated stage, the standard enthalpy $\Delta_{p}^{\text{H}}$ and entropy $\Delta_{p}^{\text{S^p}}$ of hybridization were extracted from the temperature dependence of the fluorescence issued from a solution containing the investigated complementary strands (Figure 4a). In 1.25 mM Mg(\text{OH})\(_{2}\), 25 mM NaOH, and 55 mM Hepes buffer, pH 7.5 at 20 °C, supplemented with 0.1% PDMA, $A_1$ and $P$ were titrated in 2 $\mu$L of solution at 2 $\mu$M and 3 $\mu$M in 1.25 mM Mg(\text{OH})\(_{2}\), 25 mM NaOH, and 55 mM Hepes buffer, pH 7.5 at 20 °C, supplemented with 0.1% PDMA, and measurements were performed on a solution (Figure 4S, Supporting Information), the relaxation time $\tau_{p}^{0}$ was extracted from fitting the amplitude of the chemical oscillations. M was here added in solution at 2 $\mu$M.

Consequently, fitting the experimental data yielded the two sought for thermodynamic parameters (Figure 4a).
system transfer function plotted in the frequency domain (Figure 4b). As $k^{\text{P}_0}$ could be derived from the results of the previous denaturation experiment, $k^{\text{P}_1,0}$ and $k^{0,1}$ were next simply computed thanks to $k^{\text{P}_1,0} = k^{0,1} / k^{\text{P}_0}$, and $r_1 = 1 / (k^{0,1} P + k^{0,1})$. The whole process was iterated at different average temperatures $T_0$ and the data were subsequently analyzed according to the Arrhenius law (Table 2S and Figure 3S, Supporting Information). In the 295–305 K range, $r_1$ varies between 0.04 and 0.2 s and we found the following values for the activation energies and for the logarithms of the pre-exponential factors: $E_1,1 = 48 \pm 11$ kJ·mol$^{-1}$, $E_2,2 = 218 \pm 11$ kJ·mol$^{-1}$, $\ln r_1 = 33.4 \pm 4.4$, and $\ln r_2 = 88.7 \pm 4.4$. Now equipped with eq 7 and all the necessary kinetic parameters, we could look for conditions enabling the selective detection of $A_{11}$. For various $T_0$, we estimated the resonant complementary strand concentration and excitation pulsation using $P_{t-0}^{\text{res}} = k^{0,1} / k^{\text{P}_0}$ and $r_{t-0}^{\text{res}} = k^{0,1} / P + k^{0,1}$ respectively. Thereafter, we selected an average temperature that results in a large enough excess of probe with respect to the species to be titrated and in an angular frequency accessible to our experimental setup. At $T_0 = 306$ K, we could satisfactorily work with $P_{t-0}^{\text{res}} = 7 \mu$M and $r_{t-0}^{\text{res}} = 23.65$ rad·s$^{-1}$.

Figure 5a presents the different mixtures we injected in the microfluidic chip. Channels 1–3 contained increasing concentrations of the $A_{11}$ target, from 0.5 to 2 $\mu$M, at constant resonant concentration in the P complementary strand, 7 $\mu$M here. We also added in these solutions the two interfering compounds, the nonreactive $A_{\text{NR}}$ sequence and the $A_{\text{MB}}$ fast-exchanging beacon (their concentrations were in the micromolar range). In channel 4, we introduced the sole $A_{11}$ at 2 $\mu$M and P at 7 $\mu$M. In particular, this mixture was prepared to subsequently serve as a calibration standard, allowing the conversion into concentrations of the channels 1–3 responses. Yet filled channel 5 with $A_{\text{NR}}$ and $A_{\text{MB}}$ only, in order to control the selectivity of our protocol. Importantly, we supplemented sample 4 with 2 $\mu$M of the red-emitting molecular beacon M to monitor the amplitude and phase of the temperature modulation.

The titration experiment was performed at $T_0 = 306$ K and with a $\beta = 0.002$ thermal forcing at angular frequency 23.65 rad·s$^{-1}$. Using a camera synchronized to the current generator, we recorded the fluorescence intensity variations in both green and red colors during 625 oscillations (166 s). Then, we converted the collected movie in a one-period-long video. First, complete time-averaging of the latter yielded the green image displayed in Figure 5b. It corresponds to the result that would be obtained without any thermal modulation, that is, when an equilibrium titration is performed at constant temperature $T_0$ (see Experimental Section). As expected from the close amounts of fluorescent label in solution, the emissions from the five channels were nearly similar. Furthermore, the extracted $A_{11}^{t-0}$ values were clearly larger than the various target concentrations $A_i$. Subsequently, taking advantage of the knowledge of the temperature phase measured on the red image and relying on a phase-sensitive detection scheme,\textsuperscript{23–25,51,52} we extracted for each pixel the amplitude of the green fluorescence oscillations in quadrature with the thermal excitation (see Experimental Section).\textsuperscript{53} As shown in Figure 5c, the out-of-phase responses arising from the five channels were now different. The signal from sample 5, which did not include the sought for reactant, was completely extinguished. This observation agreed with the identical responses from channels 3 and 4, which contained the same amount of $A_{11} + P$ but with and without interfering compounds. In addition, the signal increased from samples 1 to 3, in line with the $A_{11}$ concentration variation. Thanks to the channel 4 standard, these data could even be quantitatively analyzed: we titrated 0.38 ± 0.1, 0.95 ± 0.1, and 2.03 ± 0.1 $\mu$M in target whereas 0.5, 1, and 2 $\mu$M had been introduced in solution.\textsuperscript{54}

Thus, the “temperature modulation and quadrature detection” protocol completely eliminated the contribution of the nonreactive species: in marked contrast with the results obtained upon titration at chemical equilibrium, it led to $A_i^{t-1\cos} = A_i$.

**CONCLUSIONS**

Acquiring with a $\pi/2$ phase delay the signal originating from a mixture of two-state exchanging reactants submitted to a periodic thermal excitation allows one to discriminate—without any separation or washing step—a species of interest among various interfering compounds. Application to titration of what can be considered as a “thermokinetic band-pass filter” holds promises for selective and quantitative analyses. This approach has here been demonstrated by use of fluorescent microscopy, but it is generic. Whatever the observable (e.g., UV–vis or IR absorbance, refractive index), both limit-of-detection and dynamic range are at least the ones of the considered spectroscopy. Moreover, the present strategy will certainly be valuable when one has to look for minor components, a situation often
encountered in biology.\textsuperscript{1,5,11} Resonant conditions are robust and easy to achieve as far as in vitro assays are concerned. In particular, an implementation to sensors and microarrays could particularly benefit the development of label-free detection techniques, the latter being presently hampered by experimental drifts and by a lack of selectivity with respect to nonspecifically adsorbed species.\textsuperscript{12,14,27} Finally, compatibility with optical microscopy might be profitable in cell imaging, where contrast maps based on some specific biomolecule concentration should help to investigate reaction networks in vivo.

## ACKNOWLEDGMENT

This work was supported by two research fellowships from the Ministère de la Recherche et de la Technologie (to H.B. and E.C.) as well as grants “T-Wave” from the ANR blanche 2006 program and “T-ModSync” from the Cnano IdF 2008 program. We thank the LPN clean room and workshop staff for technical assistance.

## REFERENCES

(44) We did not notice any significant decrease in the amplitude of the fluorescent oscillations during the course of the measurements. The photochemical half-life associated with the present illumination settings and the present chromophores is thus several times larger than the duration of our longest acquisition, that is, $\sim 390$ s.

(45) Contrary to what has been done for the sake of readability in the Theory section, we here clearly indicate with a subscript A that the thermokinetic parameters are the ones associated with the $A_1 \rightleftharpoons A_2$ reaction. More concise notations will be adopted when several reactive couples will be mixed together. For instance, $Z_A^0$ will be used instead of $Z_A^{0_A}$ and $Q_{ij}$ instead of $Q_{ij}^{0_A}$.

(46) Although $P$ is here introduced at a concentration just 3 times higher than $A_{11}$, the "large excess" assumption holds because it yields no significant discrepancy with respect to the exact $\tau_0^A$ computation. More precisely, the present simplification, that is, $\tau_0^A = 1/(k_{t,0}^A P + k_{t,1}^A)$ with $P = 3 \mu M$, introduces a systematic error that has been estimated to be less than $\sim 5\%$; conversely, uncertainties on experimental data can be up to 20\% (see Table 2S in the Supporting Information for examples).

(47) This estimate is based on $\Delta_{MB} H = -136$ kJ⋅mol$^{-1}$ and $\Delta_{MB} S = -450$ J⋅K$^{-1}$⋅mol$^{-1}$, values for the standard enthalpy and entropy of folding which are given in Barilero, T. Imagerie de la Cinétique Chimique par Modulation de Température: Conception, Validation et Mise en Œuvre. Ph.D. thesis, Université Pierre et Marie Curie, Paris, 2009.

(50) These experimental conditions are not exactly equal to the resonance ones. Indeed, the kinetic data extracted from Figure 3S in the Supporting Information leads to $P_{res}^{0_A} = 1/K_{t,0}^A P + K_{t,1}^A$ and $\omega_{res}^{0_A} = k_{t,1}^A P_{res}^A + k_{t,1}^A = 37.72$ rad⋅s$^{-1}$ at 306 K. Thus, rigorously, we should have used the latter probe concentration and excitation pulsation. However, only a limited number of frequencies are accessible to our video acquisition setup (see Experimental Section) and we were obliged to retain slightly different settings. Nevertheless, selective titration could be achieved thanks to the nonzero bandwidth of the filter function displayed in Figure 1b.

(53) Phase-sensitive detection (PSD) is recognized to be a narrow-band technique allowing the elimination of noise at frequencies that are distinct from the excitation one.$^{24-27}$ However, it is here implemented numerically using a limited sampling rate in the time domain; thus, we do not know to what extent we still benefit from the latter advantage. We are presently developing an analogical PSD relying on a modulated illumination, as described by Braun and Libchaber,$^{28}$ and we will therefore soon be able to compare the signal-to-noise ratios provided by both approaches.

(54) The precision of the titration can be estimated by computing the standard deviation of the pixel intensity over the microfluidic channel surface. Even if values around 0.01 $\mu M$ were found, we have decided to display 10 times larger error bars. Indeed, we noticed that sometimes measurement accuracy was degraded by experimental issues such as the presence of dust or imperfect matching between the titration image and the flat-field one.
